Prevalence of asymptomatic bacteriuria among pregnant women in Kashmir
Shamweel Ahmad, Shehla Shakooh, Sajad Ahmad Salati, Abdul Muniem

Abstract

Objective: To determine the prevalence of asymptomatic bacteriuria in pregnant women and antimicrobial susceptibility pattern of pathogens isolated and also to determine the relationship between asymptomatic bacteriuria and pyuria.

Methods: A total of 392 urine specimens were collected from 392 pregnant women with asymptomatic bacteriuria attending different antenatal care clinics for regular perinatal care between April, 2007 and July, 2008. All specimens were processed using standard microbiological procedures. All the subjects were evaluated for bacteriuria.

Results: The prevalence of asymptomatic bacteriuria was 6.1% among the pregnant women in Srinagar. From 92 (23.5%) patients who had ≥5 pus cells per high power field, only 15 (16.3%) had positive urine culture. E.coli (~71%) was the commonest causative agent of asymptomatic bacteriuria followed by Klebsiella pneumoniae (~17%), group B Beta haemolytic Streptococcus (8.3%) and Proteus mirabilis (4.2%). Ciprofloxacin was found to be highly sensitive against all isolates.

Conclusion: Screening of bacteriuria in pregnancy and proper treatment must be considered as an essential part of antenatal care in this community. To prevent asymptomatic bacteriuria complications, all pregnant women should be screened at the first antenatal visit. A negative test for pyuria is not a reliable indicator of the absence of asymptomatic bacteriuria in pregnant women.

Key words: asymptomatic bacteriuria, pyuria, antenatal care, urinary tract infection, E. coli

Introduction

Urinary tract infection (UTI) is one of the most common diseases encountered in clinical practice today. Urinary tract infection is not only common but the range of clinical effect varies from asymptomatic bacteriuria to acute pyelonephritis. Urinary tract infection is the commonest of all bacterial infections, affecting human beings throughout their life span especially in women. Nearly 50% of all women develop symptoms of urinary tract infection at some stage during their life. Urinary tract infection account for more than 7 million visits to physicians and necessitate over 1 million hospital admissions in USA annually. The urinary tract undergoes profound physiological and anatomical changes during pregnancy facilitating the development of bacteriuria both symptomatic and asymptomatic in women. Symptomatic bacteriuria is the tip of an iceberg of total bacteriuria. Pregnancy is a provocation for the asymptomatic to become symptomatic. About 10% of those with asymptomatic bacteriuria develop symptomatic bacteriuria during pregnancy. Symptomatic bacteriuria is easily diagnosed and treated due to its overt symptoms. But asymptomatic bacteriuria is difficult to diagnose and it is more common in pregnant women than non-pregnant women. In pregnancy, 30-40% of untreated pregnant women with asymptomatic bacteriuria develop acute pyelonephritis in late pregnancy. Pyelonephritis is associated with significant morbidity during pregnancy for the mothers and the fetus. Thus, exact screening and treatment of bacteriuria regardless of symptoms is a must in order to avoid further complications. Anatomic and physiologic changes that occur during the pregnancy increase the risk of pyelonephritis in this period. This is mostly because pregnancy is a common cause of obstructive uropathy and thus results in severe renal infections. As pyelonephritis usually arises from preexisting bacteriuria; experts recommend screening and eradication of silent infections as routine prenatal...
practice. Early treatment of asymptomatic bacteriuria decreases the risk of pyelonephritis in the later stages of pregnancy by at least 75%. Also there is evidence that when there is no symptom, untreated bacteriuria in pregnancy may lead to less favorable pregnancy outcomes and complications like preterm delivery, low birth weight, pre-eclampsia toxemia and anemia of pregnancy. Stenqvist and colleagues have shown that 18 weeks of gestation is the optimal time for performing screening culture for detecting bacteriuria. The present study was undertaken to determine the prevalence of asymptomatic bacteriuria in pregnancy; its causative agents and their antimicrobial susceptibility pattern, and also to determine the relationship between asymptomatic bacteriuria and pyuria.

Materials and methods
The study was conducted in the city of district Srinagar, Kashmir, India. A total 392 urine specimens were collected from asymptomatic bacteriuric women during April, 2007 to March, 2008. All subjects were examined at the first antenatal visit and maximum gestational age was 18 weeks. None of the patients had any signs or symptoms of classical UTI on examination. Asymptomatic bacteriuria was defined as the presence of ≥10^5/ml colonies of the same bacterial species in two consecutive midstream urine without any symptom of urinary tract infection. On each visit, two consecutive midstream clean catch urine samples, one on the day of the visit and another on the next day of the visit, were collected in a sterile wide mouth screw capped container with aseptic precautions. The patients were individually instructed about the technique for collecting clean voided midstream urine specimens. All patients were asked to wipe their labia with soapy water and rinse well, then after urinating a little in the toilet fill the container (clean catch method). All the specimens were sent to the microbiology laboratory and processed on the same day. Standard microbiological techniques were used in the culture of all MSU specimens and in the identification of the isolates. One μl of uncentrifuged urine specimens were aseptically inoculated, using standard loops, onto sheep blood agar (SBA) plates containing 6% blood and cysteine lactose electrolyte deficient (CLED) agar plates. The plates were incubated aerobically for 24 to 48 hours at 37°C. The plates were read at the end of the incubation period. Colony counts equal to or more than 10^5/ml was considered as significant growth.

Antibiotic susceptibility testing was carried out using the Kirby-Bauer disc diffusion technique on Muller-Hinton agar and commercial antibiotic discs (Oxoid, United Kingdom) were used for antimicrobial testing. The antibiotic discs used were: Ampicillin (10 μg), Naldixic Acid (30 μg), nitrofurantoin (300μg), Cephalexin (30 μg), Gentamicin (10 μg), Trimethoprim-Sulphamethoxazole (1.25/ 23.75 μg) and Ciprofloxacin (5 μg). The antibiotic disc impregnated culture plates were incubated at 37°C overnight. The diameter of the zone of inhibition was measured and recorded as resistant or susceptible according to the National Committee for Clinical Laboratory Standards (NCCLS) interpretative criteria. For the test of proteinuria, the end of the reagent strip was dipped in the fresh urine for approximately 1 second and shaken off by tapping the strip on the side of the container. After 30 to 60 seconds the test strip was compared with the color scale (color range from yellow for “negative” and through yellow-green and green blue for “positive”). For microscopy about 10 ml of well-mixed urine sample was centrifuged at 2000xg for 5 minutes. A drop of the deposit was examined microscopically at 40x for the presence of pus cells, red blood cells, epithelial cells, casts and crystals.

The Statistical Package for Social Sciences (SPSS, version 10.1) was used for data analysis. The results are expressed as mean value ± standard deviation. Chi-square test was used for comparison between groups. A two-tailed p-value less than 0.05 was considered statistically significant.

Results
The total number of participants who finished the study was 392. The mean age of the participants was 27.4 ± 3.1(range, 19-37 years). Of the 392 urine specimens processed, 24 (6.1%) showed significant bacteriuria. Thus the prevalence of different types of causative organism of significant bacteriuria was 6.1%. The frequency of the microorganisms isolated is shown in Table 1. The commonest organism causing bacteriuria was Escherichia coli. The sensitivity pattern of the isolated organisms revealed that all were sensitive to ciprofloxacin and gentamicin at very high percentage (Table 2). The organisms showed resistance to currently preferred urinary antibiotics and chemotherapeutic agents like co-trimoxazole, norfloxacin, and cephalexin (Table 2). Ninety-two (23.5%) women had more than 5 pus cells in urine specimens from which 15 (16.3%) had positive cultures. Association of presence of pus cells with bacterial growth is shown in Table 3. Women with higher number of pus cells in urine specimen had significantly higher asymptomatic bacteriuria (p<0.0001).

Prevalence of asymptomatic bacteriuria among pregnant women in Kashmir

Discussion

Urinary tract infections are remarkably common in women. Some 20% women in the age range 20-65 years suffer from at least one attack per year, 50% develop a urinary tract infection within their lifetime. Not surprisingly infections of the urinary tract are the most common bacterial infections encountered during pregnancy. These can be both symptomatic and asymptomatic. Asymptomatic bacteriuria during pregnancy is a common and important medical condition, which will result in overt renal infections such as pyelonephritis if not detected and treated. Small showed that on average treating 7 pregnant women with asymptomatic bacteriuria results in prevention of one episode of pyelonephritis. Ten percent of pregnant women attended in an antenatal clinic had symptomatic urinary tract infections. In another study by Khatun et al. (1985), it was found that 30% of clinically healthy pregnant women had asymptomatic bacteriuria. Findings of the present community based study indicate that the asymptomatic bacteriuria in pregnancy is a major health problem in Srinagar city. Observed from this study that E. Coli was the commonest pathogen responsible for bacteriuria. It is consistent with the findings of Rahman et al. (1990) and Ahmed et al. (1996). Like the other studies, the findings of our study also indicate that ciprofloxacin is highly effective. The most effective in-vitro agents were found to be gentamicin among the injectables and ciprofloxacin among the orally administered ones. Other useful oral antibiotics were nitrofurantoin and nalidixic acid. The organisms showed resistance to currently preferred urinary antibiotics and chemotherapeutic agents like co-trimoxazole and cephalaxin. Our findings were in agreement with a study from Kashmir. It may probably be due to less use of ciprofloxacin since it is comparatively a newer introduction and also costly. This fact indicates that urinary pathogens became resistant day by day to the commonly used antibiotics in our country. This may be due to wide spread and indiscriminate use of the drugs. There are many studies that link so many pregnancy complications like hypertensive disorders in pregnancy, low birth weight, premature with asymptomatic bacteriuria. Moreover, for the last two decades, asymptomatic bacteriuria has also been identified as a risk factor of similar pregnancy complications. The results of the present study also agree with these findings. The association between asymptomatic bacteriuria and prematurity is established. But the mechanism is not well defined yet. Several investigators have observed a high incidence of pyelone-phritis in bacteriuric pregnant mothers.

In this study, prevalence of asymptomatic bacteriuria was found to be 6.1%, which is in agreement with others. We also found that asymptomatic bacteriuria was associated with lower maternal age. The prevalence of asymptomatic bacteriuria was reported to be as high as 21% in a study from Ibadan city, Nigeria and 86.6% in another study from Benin City, Nigeria. Significant pyuria with bacteriuria was found in 62% of our patients. So the presence of significant pyuria should not be used as a screening test for asymptomatic bacteriuria in pregnancy. Using this method for screening of asymptomatic bacteriuria in this study would have obtained a false negative rate of 40%. This is consistent with the results of other studies. Two studies found that there was only 50% significant pyuria with positive cultures.

Pyuria was found in 21% of negative cultures. In two others studies, pyuria has been reported in in up to 30% and 23% of negative cultures. They concluded that all samples should be sent for culture, because none of the rapid tests, including the screen for pyuria, are reliable for detecting asymptomatic bacteriuria in pregnant women. Wadland and colleagues showed that screening for asymptomatic bacteriuria is cost saving unless the prevalence of asymptomatic bacteriuria falls below 2%, the risk of pyelonephritis with asymptomatic bacteriuria falls below 13%, or the efficacy of treatment in preventing pyelonephritis falls below 38%. Thus, in our region, this intervention remains cost saving. Finally, in accordance with Stengvist and colleagues, we chose 18 weeks gestation as the optimal time to perform the screening culture in order to maximize the chances of detecting bacteriuria. However, in North America the current approach is to screen for asymptomatic bacteriuria at 12 weeks of gestation.

In conclusion, screening for bacteriuria in pregnancy and proper treatment must be considered as an essential part of antenatal care in this community. A negative test for pyuria is not a reliable indicator of the absence of asymptomatic bacteriuria in pregnant women. Thus, all urine specimens, regardless of leukocyte count, should be sent for culture and sensitivity.
